

Understanding the spatial distribution of housing prices is crucial for real estate investment, urban planning, and socioeconomic policy formulation. Housing property values are rarely distributed randomly; instead, they display strong spatial dependence and clustering driven by geographic accessibility, urbanization, and environmental amenities.

This report provides a geospatial evaluation of property values across California using QGIS and spatial coordinate vector datasets.

The figural analysis reveals that housing prices in California exhibit clear geographic clustering rather than random distribution. High-value properties are primarily concentrated in coastal metropolitan regions, particularly around the San Francisco Bay Area, while inland areas generally show lower housing prices.

These findings suggest that geographic location is a key factor influencing housing values. The visualization highlights how GIS can effectively uncover regional market patterns that are difficult to identify from tabular data alone.
